Flow and Transformations in Porous Media

2 ABSTRACT

3   Flow in porous media is a significant challenge to many computational fluid dynamics methods
4 because of the complex boundaries separating pore fluid and host medium. However, the rapid
5 development of the lattice Boltzmann methods and experimental imaging techniques now allow
6 us to efficiently and robustly simulate flows in the pore space of porous rocks. Here we study the
7 flow and dispersion in the pore space of limestone samples using the unstructured, characteristic
8 based off-lattice Boltzmann method. We use the method to investigate the anomalous dispersion
9 of particles in the pore space. We further show that the complex pore network limits the effectivity
10 by which pollutants in the pore space can be removed by continuous flushing. In the smallest
11 pores, diffusive transport dominates over advective transport and therefore cycles of flushing
12 and no flushing, respectively, might be a more efficient strategy for pollutant removal.

13 Keywords: Lattice Boltzmann method, flow in porous media, dispersion in porous media, unstructured grids, numerical modelling

1 INTRODUCTION

14 Recent numerical simulations of flow in porous media in both two and three dimensions have revealed
15 highly non-trivial flow patterns. Particles passively advected by the flow in the pore-space, so-called
16 Lagrangian particles, follow trajectories with periods of almost stagnation punctuated by bursts of fast
17 fluctuating motion (**de Anna et al.**, 2013; **Lester et al.**, 2013; **Kang et al.**, 2014). In a Berea sandstone
18 sample, it was shown by a three dimensional simulation that this intermittent behaviour was equally
19 significant in both longitudinal (the mean flow direction) and transverse directions (**Kang et al.**, 2014).
20 The chaotic Lagrangian dynamic emerges despite the fact that the inertia of the fluid is negligible in
21 many natural and industrial settings, i.e. the flow happens at low Reynolds numbers. Nonetheless, the
22 flow might exhibit a complicated spatio-temporal behavior owing to the high heterogeneity of the pore
23 space. The heterogeneity in fact gives rise to anomalous (non-Fickian) transport properties similar to those
24 typically associated to high Reynolds number flow (**Benson et al.**, 2000). The anomalous transport has
25 implications for the local dispersion of particles in a porous medium. It can alter the reaction rates of
26 transported reactants or accelerate the small scale dispersion of pollutants.

27   In addition to the strong intermittent behaviour, it has been found in both two and three dimensional
28 simulations that the velocity autocorrelation, as a function of space, is short ranged while as a function of
29 time the longitudinal velocity exhibits long time correlations. In the three dimensions, it was found (**Kang**
30 **et al.**, 2014) that the transverse velocity autocorrelation decays faster, though the absolute value is strongly
31 correlated in time, a feature also observed in turbulent flows (**Mordant et al.**, 2002). These remarkable
32 properties have led to the suggestion that the Lagrangian particle velocities is given by a Markov
33 process in space (at equidistant positions along the Lagrangian trajectories) and not in time (**Le Borgne**
34 **et al.**, 2008a,b). In a Markov process the particle motion can be seen as a correlated continuous time
35 random walk (CTRW). Using a correlated CTRW, several signatures of anomalous transport behaviour
36 were accurately reproduced such as the long tails of the first passage time distribution (**Le Borgne**
37 **et al.**, 2008a), the non-linear scaling of the second centred moment of the particles longitudinal and
38 transverse displacements (**Le Borgne et al.**, 2008a; **Kang et al.**, 2014; **Lester et al.**, 2014), the probability
39 distribution function of the Lagrangian velocity increments for different time lags among others (**de Anna**
40 **et al.**, 2013).

41   Interesting results were also obtained in the study of scalar mixing in two dimensional porous media
42 with different structural disorder (**Le Borgne et al.**, 2013). Numerical simulations showed that the scalar
43 concentration forms, at advanced time, a fractal-like structure composed of stripes of high concentration
44 and with high lacunarity. The probability distribution function of the pair separation of advecting particles
45 was fitted to a log-normal distribution and the averaged squared separation was found to grow with time as
46 a power law whose exponent depends on the geometry. For weak and strong heterogeneities of the porous
47 sample the exponents were found to be 1.8 and 2.8, respectively. Remarkably, we can see that the second
48 exponent is very close to the Richardson dispersion law, characteristic of the separation of particles whose
49 distance lie in the inertial range interval in turbulent flows. The authors proposed a stochastic model based
50 on *ad hoc* arguments to describe the behaviour of the pair separation of advecting particles $l(t)$, which
51 reflects the multiplicative nature of the stretching processes and accounts for the observed short range
52 temporal correlations of the Lagrangian stretching rates.

53   Here we formulate a version of the lattice Boltzmann method on unstructured grids to efficiently
54 simulate flow in complex pore geometries. We use the method to assess the Lagrangian dynamics of
55 flows in the pore space of limestone samples computed by x-ray tomography. In order to faithfully
56 compute the broadly distributed fluid velocities, it is required to represent the pore boundaries with a
57 high resolution. Compared to classical lattice Boltzmann methods on regular grids, the unstructured grids
58 offer a superior resolution and adaptivity (**Misztal et al.**, 2015). We further analyze the impact of the
59 complex pore geometry on pollutant removal from the pore space.

2 MATERIAL & METHODS

2.1 POROUS ROCK SAMPLES

60 We have performed our pollutant dispersion studies on two different, natural porous samples, discretized
61 using tetrahedral elements (the properties of the tetrahedral meshes are presented in Table 1).

62   *Sample A* (Fig. 1) is chalk from off-shore drilling in the North Sea region (Hod chalk #15). *Sample*
63 *B* (Fig. 2) came from an outcrop of bryozoan chalk in Rødvig, Denmark. The digital 3D images were
64 obtained by x-ray nanotomography (**Cloetens et al.**, 1999) measured at beamline ID22 at the European
65 Synchrotron Radiation Facility, France. The reconstructed volume of Sample A had a voxel size of 25
66 nm and an optical resolution about 150 nm. Details about the data collection and reconstruction can be
67 found in **Müter et al.** (2014). The reconstructed images were corrected for ring artefacts (**Jha et al.**,
68 2014) before segmentation by a dual filtering and Otsu thresholding procedure (**Müter et al.**, 2012). For
69 the LBM calculations we used a subvolume of 100^3 voxels, which gives a side length of 2.5 microns.
70 Sample B was reconstructed and segmented in the same way as Sample A. The only difference is that it
71 was reconstructed with a voxel size of 50 nm leading to an optical resolution of about 300 nm. The LBM

Table 1. Properties of the tetrahedral meshes used in the simulations and the wall-clock time spent per 5000 iterations of the unstructured lattice Boltzmann simulation (Intel®Xeon®2.6 GHz).

| | No. elements | No. vertices | edge lengths (LB) | | | side length (LB) | node valency | | | simulation time |
			avg.	min.	max.		avg.	min.	max.	per 5000 iterations
Sample A	538,818	122,923	1.48	0.082	3.4	100	11.7	4	44	7m30s
Sample B	19,011,599	4,131,911	1.51	0.22	68.0	400	12.3	4	39	4h30m

72 calculations were performed on a subvolume of 400^3 voxels (side length of 20 microns). In Sample A, the
73 diameter of the pore throats corresponds to at least 6 voxel sizes, while the typical pore diameter is 30-40
74 voxels. In Sample B, the smallest pore throats are about 5 voxels, however, the flow is dominated by a
75 large, well connected pore system, where the pore diameter is 50 voxels and above.

76   In order to construct the tetrahedral meshes, the initial triangular surface meshes were produced using
77 the marching cubes isosurface as implemented in ImageJ (**Schneider et al.**, 2012). The resolution of
78 those surface meshes is the same as in the corresponding tomographic data (1 voxel accounting for 1-2
79 triangles). A tetrahedral volume mesh was constructed from the surface mesh using Tetgen (**Si**, 2015).

2.2 UNSTRUCTURED LATTICE BOLTZMANN METHOD

80 The appeal of the lattice Boltzmann method to the geophysics research lies in its ability to model and
81 simulate several types of phenomena related to reactive fluid flow in porous rocks: single and multiphase
82 flows (**Huang et al.**, 2011), unsteady flows (**Pazdniakou and Adler**, 2013), flows in complex geometries
83 (**Pan et al.**, 2006; **Chang et al.**, 2009) at a wide range of Reynolds numbers, as well as chemical processes,
84 such as dissolution and precipitation (**Kang et al.**, 2003). For our experiments, we have used a variant
85 of the finite element, off-lattice Boltzmann method (**Bardow et al.**, 2006), which uses the characteristic
86 based integration, first proposed by **Zienkiewicz and Codina** (1995). We chose this method over the finite
87 volume approach (**Rossi et al.**, 2005; **Misztal et al.**, 2015) due to its improved stability. The characteristic
88 based, off-lattice Boltzmann method has been specifically designed to remove the coupling between the
89 positions of the computational grid's nodes and the discrete set of velocities, while retaining the stability
90 of the standard, regular grid-based approach. The new scheme is derived directly from the spatio-temporal
91 continuous formulation of the lattice Boltzmann equation

$$\frac{\partial f_i}{\partial t} + \mathbf{c}_i \cdot \nabla f_i = \Omega_i(f(\mathbf{x}, t)), \tag{1}$$

92 where $f_i(\mathbf{x}, t)$ is the particle velocity distribution along the i-th discrete direction, $\mathbf{c}_i$ is the associated
93 discrete velocity, and Ω_i is the collision operator, accounting for the rate of change of f_i due to collision.
94 We have employed the two relaxation time collision (TRT) operator (**Pan et al.**, 2006; **Talon et al.**, 2012),
95 which is a special case of a multi relaxation time collision operator (MRT, **d'Humieres et al.** (2002)),
96 most commonly used in the lattice Boltzmann studies of porous flow due to its improved treatment of the
97 solid boundary conditions in comparison to the standard, single relaxation time Bhatnagar-Gross-Krook
98 (BGK) operator (**Pan et al.**, 2006).

99 *2.2.1 Integration along characteristics.*   Integrating Eq. (1) along the characteristic curves and
100 approximating the right-hand side yields

$$f_i^{n+1}(\mathbf{x} + \mathbf{c}_i \delta t) = f_i^n(\mathbf{x}) + \delta t \left(\theta \Omega_i^{n+1}(f^{n+1}(\mathbf{x} + \mathbf{c}_i \delta t)) + (1 - \theta) \Omega_i^n(f^n(\mathbf{x})) \right), \tag{2}$$

101 where n denotes the time step (iteration number), $0 \leq \theta \leq 1$ refers to the choice of the time integration
102 method for the collision operator (0 for fully explicit, 1 for fully implicit, 0.5 for Crank-Nicolson),

103 $f_i^n(\mathbf{x}) = f_i(\mathbf{x}, t^n)$, and $f_i^{n+1}(\mathbf{x}) = f_i(\mathbf{x}, t^n + \delta t)$. In the general case of a MRT collision operator
104 $\Omega_i(f(\mathbf{x}, t)) = \sum_j A_{ij}(f_j^{eq} - f_j)$ (**d'Humieres et al.**, 2002) the implicit character of Eq. (2) can be
105 removed by introducing new variable

$$g_i(\mathbf{x}, t) = f_i(\mathbf{x}, t) - \delta t \theta \, \Omega_i(f(\mathbf{x}, t)), \tag{3}$$

106 and expressing the collision operator in terms of g (**Bardow et al.**, 2006)

$$\mathbf{\Omega}(f(\mathbf{x}, t)) = (\mathbf{I} + \delta t \theta \mathbf{A})^{-1} \mathbf{\Omega}(g(\mathbf{x}, t)). \tag{4}$$

107 As the collision operator preserves both mass and momentum, the moments of g_i equal corresponding
108 moments of f_i, $\sum_i g_i = \rho$, $\sum_i g_i \mathbf{c}_i = \rho \mathbf{u}$, hence also $g_i^{eq} = f_i^{eq}$. Finally, Eq. (2) becomes

$$g_i^{n+1}(\mathbf{x} + \mathbf{c}_i \delta t) = g_i^n(\mathbf{x}) + \delta t \sum_j \hat{A}_{ij}(g_j^{eq,n}(\mathbf{x}) - g_j^n(\mathbf{x})), \tag{5}$$

109 where the modified collision matrix reads $\hat{\mathbf{A}} = (\mathbf{I} + \delta t \theta \mathbf{A})^{-1} \mathbf{A}$. By substituting $\mathbf{A}$ by $\mathbf{A}_{BGK} = \tau^{-1} \mathbf{I}$,
110 which corresponds to the single relaxation time BGK collision operator, one readily obtains $\hat{\mathbf{A}}_{BGK} =$
111 $(\tau + \theta \delta t)^{-1} \mathbf{I}$. The resulting shift in the effective relaxation time $\hat{\tau} = \tau + \theta \delta t$ accounts for the unconditional
112 stability of the Crank-Nicolson method and the implicit Euler method, since the condition $\delta t < 2\hat{\tau}$ is
113 always fulfilled as long as $\theta \geq \frac{1}{2}$ and $\tau > 0$. The standard Courant-Friedrichs-Lewy restriction on δt still
114 applies.

115 *2.2.2 Finite element scheme.* In order to solve Eq. (5) numerically on an unstructured grid, one has to
116 be able to express the value of g_i^{n+1} at a given point $\mathbf{x}^*$ in terms of the value of g_i^n (and its derivatives)
117 evaluated one time step earlier, at the same point. In order to enhance stability, this is typically done by the
118 second order Taylor expansion of $g_i^n(\mathbf{x}^* - \mathbf{c}_i \delta t)$ (**Zienkiewicz and Codina**, 1995; **Bardow et al.**, 2006)

$$g_i^n(\mathbf{x}^* - \mathbf{c}_i \delta t) = g_i^n(\mathbf{x}^*) - \delta t c_{ir} \partial_r g_i^n(\mathbf{x}^*) + \frac{\delta t^2}{2} c_{ir} c_{is} \partial_s \partial_r g_i^n(\mathbf{x}^*) + \mathcal{O}(\delta t^3). \tag{6}$$

119 After applying the same approximation to the equilibrium distribution function, Eq. (5) takes the following
120 form

$$
\begin{aligned}
g_i^{n+1} = g_i^n - \delta t &\left(c_{ir} \partial_r g_i^n - \sum_j \hat{A}_{ij}(g_i^{eq,n} - g_i^n) \right) \\
+ \frac{\delta t^2}{2} c_{ir} \partial_r &\left(c_{is} \partial_s g_i^n - 2 \sum_j \hat{A}_{ij}(g_i^{eq,n} - g_i^n) \right) + \frac{\delta t^3}{2} c_{ir} c_{is} \partial_s \partial_r \left(\sum_j \hat{A}_{ij}(g_j^{eq,n} - g_j^n) \right),
\end{aligned}
\tag{7}
$$

121 which is now suitable for discretization in space using the Galerkin finite element method. Here, the spatial
122 decomposition using linear, tetrahedral elements has been applied. The modified particle distribution
123 functions are sampled at the nodes (vertices) of the tetrahedral mesh, and interpolated at other points

$$\tilde{g}_i^n(\mathbf{x}) = \boldsymbol{\phi}(\mathbf{x})^T \tilde{\mathbf{g}}_i^n \tag{8}$$

124 where $\tilde{g}_i^n$ is the approximate solution, $\tilde{\mathbf{g}}_i^n = \left[\tilde{g}_i^n(\mathbf{v}_1), \tilde{g}_i^n(\mathbf{v}_2), \dots, \tilde{g}_i^n(\mathbf{v}_{N_V}) \right]^T$ is the vector storing the
125 values of $\tilde{g}_i^n$ at all vertices in the mesh, whose positions are $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_{N_V}$. Furthermore, $\boldsymbol{\phi}(\mathbf{x})^T =$

126 $[\phi^1(\mathbf{x}), \phi^2(\mathbf{x}), \ldots, \phi^{N_V}(\mathbf{x})]$, where $\phi^k(\mathbf{x})$ is a piecewise-linear shape function (also known as a *hat* or
127 *tent* function) associated with the vertex k, i.e. $\phi^k(\mathbf{v}_j) = \delta_{jk}$, and ϕ^k is linear over each tetrahedral
128 element. By applying the Bubnov-Galerkin method, we finally obtain the discrete, weak form of Eq. (7)

$$\mathbf{M}(\tilde{\mathbf{g}}_i^{n+1} - \tilde{\mathbf{g}}_i^n) = \left(-\delta t \mathbf{C}_i - \delta t^2 \mathbf{D}_i\right) \tilde{\mathbf{g}}_i^n + \left(\delta t \mathbf{M} - \delta t^2 \mathbf{C}_i - \delta t^3 \mathbf{D}_i\right) \sum_j \hat{A}_{ij}(\tilde{\mathbf{g}}_j^{eq,n} - \tilde{\mathbf{g}}_j^n), \qquad (9)$$

129 where matrices $\mathbf{M}, \mathbf{C}_i, \mathbf{D}_i \in \mathbb{R}^{N_V \times N_V}$ are defined as

$$\mathbf{M} = \int_{\mathcal{D}} \phi \phi^T dV, \quad \mathbf{C}_i = \int_{\mathcal{D}} \phi c_{ir} \partial_r \phi^T dV, \quad \mathbf{D}_i = \frac{1}{2} \int_{\mathcal{D}} \partial_s \phi c_{is} c_{ir} \partial_r \phi^T dV. \qquad (10)$$

130 *2.2.3 Boundary conditions.* The quality of any lattice Boltzmann simulation hinges on the choice
131 of the boundary conditions used both on the solid and open boundaries. In this work, we have used a
132 recent formulation of the solid boundary conditions for high Reynolds number flows, first proposed by
133 **Chikatamarla and Karlin** (2013). Similarly to the popular bounce back method, the first step is to
134 determine the subset $\bar{D}$ of the discrete directions that are corresponding to the "missing" populations (i.e.
135 point away from the solid phase and into the fluid phase). The procedure for finding such subset in an
136 unstructured grid setting is described in detail in **Misztal et al.** (2015). By setting the target values of the
137 density ρ_{tg} and velocity $\mathbf{u}_{tg}$ at the boundary node, the local populations are recovered using the following
138 rules

$$f_i \longleftarrow \begin{cases} 2f_i^{eq}(\rho_{tg}, \mathbf{u}_{tg}) - f_i^{eq}(\rho, \mathbf{u}), & i \in \bar{D} \\ \\ f_i + f_i^{eq}(\rho_{tg}, \mathbf{u}_{tg}) - f_i^{eq}(\rho, \mathbf{u}), & i \notin \bar{D} \end{cases}, \qquad (11)$$

139 where $\rho = \sum_{i \in \bar{D}} f_i^{eq}(\rho_{tg}, \mathbf{u}_{tg}) + \sum_{i \notin \bar{D}} f_i$, and $\rho\mathbf{u} = \sum_{i \in \bar{D}} \mathbf{c}_i f_i^{eq}(\rho_{tg}, \mathbf{u}_{tg}) + \sum_{i \notin \bar{D}} \mathbf{c}_i f_i$. In our
140 simulations we assumed no-slip boundary condition on the static, solid walls, corresponding to $\mathbf{u}_{tg} = 0$.
141 The value of ρ_{tg} can be estimated either by using the bounce back method or, if the former approach fails
142 (depending on the local geometry of the solid boundary), by extrapolating the values of density from the
143 neighbouring bulk nodes. We have observed that this choice of the solid boundary condition formulation
144 yields significantly more stable simulations of flows with lower values of the kinetic viscosity and higher
145 Reynolds number, compared to the bounce back method.

146 The boundary conditions at the inlet and at the outlet can also be implemented using the same procedure.
147 We have chosen to use pressure boundary conditions, specified by the constant pressure values: p_{in} at the
148 inlet, and p_{out} at the outlet; $p_{in} > p_{out}$. Since $p = c_s^2 \rho$ in the lattice Boltzmann method, this is equivalent to
149 setting $\rho_{tg} = p_{in}/c_s^2$ at the inlet and $\rho_{tg} = p_{out}/c_s^2$ at the outlet (like most authors, we use $c_s^2 = 1/3$). The
150 values of $\mathbf{u}_{tg}$ at the open boundary nodes can be approximated using the averaged values of the velocity
151 at the neighbouring bulk nodes.

3 RESULTS

152 The unstructured lattice Boltzmann method allows us to robustly compute single phase flow fields in
153 arbitrary, complex channel networks for a wide range of flow parameters. In this section, we apply this
154 method to study the flow in each of the natural porous samples described in Section 2.1. We then use the
155 precomputed flow fields to study pollutant dispersion in the samples.

3.1 STEADY-STATE FLOW COMPUTATION

156 Our first goal is to compute the steady state flow in each porous rock sample due to applying a constant
157 pressure difference between the inlet and the outlet planes. The particle distribution functions are

158   initialized with the equilibrium distributions corresponding to $\rho = 1$, $\mathbf{u} = 0$ in the entire mesh. For a given
159   time step δt, relaxation time τ, and constant inlet and outlet densities $\rho_{in} = 1 + \Delta\rho$ and $\rho_{out} = 1$, we
160   run the lattice Boltzmann simulation until the steady state is reached. In order to detect when steady-state
161   has been reached, we compute the inlet flow rate Q_{in} by evaluating the following integral numerically at
162   every time step t^n

$$Q_{in} = \int_{A_{in}} \mathbf{u} \cdot d\mathbf{A} \approx \sum_{T_k = \langle pqr \rangle} \frac{\mathbf{u}_p + \mathbf{u}_q + \mathbf{u}_r}{3} \cdot \mathbf{n}_k A_k, \tag{12}$$

163   where the sum on the right-hand side is over each inlet triangle T_k; $\mathbf{u}_p$, $\mathbf{u}_q$, $\mathbf{u}_r$ are its nodal velocities, $\mathbf{n}_k$ is
164   the unit-length normal vector to T_k, and A_k is its area. The outlet flow rate Q_{out} is evaluated the same way.
165   The simulation ends when $|Q_{in}(t^{n+1}) - Q_{in}(t^n)| < \epsilon |Q_{in}(t^n)|$ and $|Q_{out}(t^{n+1}) - Q_{out}(t^n)| < \epsilon |Q_{out}(t^n)|$,
166   where $\epsilon = 10^{-5}$.

167   Examples of the obtained velocity fields in each of the porous samples are shown in Figures 1 and 2.
168   In Figure 3 we present the typical convergence plots for Q_{in} and Q_{out} in our simulations. The initial
169   oscillations are caused by the discontinuous initial conditions, as well as the formulation of the open
170   boundary conditions; setting $\rho_{in} = 1 + \Delta\rho$ gives rise to a shock wave, which first travels to the outlet, and
171   gets reflected off the outlet and inlet planes, while its amplitude decays exponentially. Once the pressure
172   wave vanishes, the values of Q_{in} and Q_{out} continue to converge exponentially to the steady state values
173   Q_{in}^∞ and Q_{out}^∞. We expect these values to be equal, however, since the expression (12) is only first-order
174   accurate, we observe a small difference between these two values, which is particularly evident in case of
175   the more coarsely meshed Sample A. We have performed steady-state flow computation for $\Delta\rho$ ranging
176   from $2.5 \cdot 10^{-7}$ to $2.5 \cdot 10^{-3}$, and relaxation times $\tau = 0.01 - 0.1$, and we have obtained stable results
177   obeying the Darcy's law, which states that under steady-state flow conditions, the flow rate Q through a
178   given cross section is proportional to the pressure drop $\Delta p = c_s^2 \Delta\rho$ that drives the fluid.

179   These simulation results shown in Figures 1 and 2 correspond to a Reynolds number approximately
180   equal to 0.01. The velocity in the figures is expressed in lattice Boltzmann units u_{LB}. By dimensional
181   analysis we can express the velocity in another arbitrary system of units according to the following
182   transformation

$$u_{SU} = u_{LB} \frac{l_{LB}}{l_{SU}} \frac{\nu_{SU}}{\nu_{LB}}, \tag{13}$$

183   where the l_{LB} and ν_{LB} are the system size and kinetic viscosity in lattice Boltzmann units, l_{SU} and ν_{SU}
184   are the same quantities expressed in another system of units. If the fluid is water, substituting the real-
185   world parameters into Eq. (13) yields the following scaling formulas for the real-world velocities in the
186   SI system of units: $u_{SI} = u_{LB} \cdot 6000 \frac{\mathrm{m}}{\mathrm{s}}$ in Sample A, and $u_{SI} = u_{LB} \cdot 600 \frac{\mathrm{m}}{\mathrm{s}}$ in Sample B.

3.2   DISPERSION IN POROUS SAMPLES

187   Having computed the steady state flow field in each of the porous rock samples, we obtain the Lagrangian
188   trajectories of passive tracers, which satisfy

$$\dot{\mathbf{x}}_k(t) = \mathbf{u}(\mathbf{x}_k(t)), \tag{14}$$

189   in the absence of molecular diffusion. The solution of the above equation is fixed by the initial position
190   $\mathbf{x}_k(0)$. From these Lagrangian trajectories we study the statistics of the separation $\mathbf{d}_{kj}(t) = \mathbf{x}_k(t) - \mathbf{x}_j(t)$
191   between two fluid particles, which initially are close to each other. The separation of particles obeys the
192   differential equation

$$\dot{\mathbf{d}}_{kj}(t) = \mathbf{u}(\mathbf{x}_k(t)) - \mathbf{u}(\mathbf{x}_j(t)). \tag{15}$$

193   The constraints imposed by the porous heterogeneous structure may cause non-smooth velocity fields due
194   to the intrinsic branching of channel connectivity, leading to broad distribution of velocities and absence

195 of decorrelation in time. For non-smooth velocity fields we might have, for instance, that the velocity
196 difference between two points scales as $|\mathbf{u}(\mathbf{x}_k(t)) - \mathbf{u}(\mathbf{x}_j(t))| \propto |\mathbf{x}_k(t) - \mathbf{x}_j(t)|^\beta = d_{kj}^\beta$, with $\beta < 1$, as
197 in the inertial range in turbulent flows. Multiplying the left and right hand sides terms in (15) by $\mathbf{d}_{kj}(t)$
198 and substitution of the latter scaling lead to

$$\dot{d}^2 = 2\,\mathbf{d}_{kj} \cdot [\mathbf{u}(\mathbf{x}_k(t)) - \mathbf{u}(\mathbf{x}_j(t))] \propto d^{1+\beta}, \tag{16}$$

199 whose solution for finite time gives the behaviour

$$\left(\frac{d(t)}{d_0}\right)^2 \propto t^{\frac{2}{1-\beta}}. \tag{17}$$

200 As seen in Figure 4, we find from a flow simulation in Sample A that $\beta \approx 1/3$, which coincides with
201 Richardson dispersion law. Of course, such spatial scaling should not be associated to the classical
202 Richardson-Kolmogorov cascade picture. Instead, the anomalous dispersion originates from the high
203 degree of heterogeneity in Sample A and the broad distributions of pore sizes. This is further confirmed by
204 the simulations performed in Sample B, here we see a particle separation in time, which is consistent with
205 ballistic motion of particles in a more simple geometry. This is due to the fact, that the flow in Sample B is
206 dominated by one large pore and the heterogeneity of the much smaller neighboring pores is only having
207 a negligible impact on the averaging (see Fig. 4).

3.3 EVACUATION OF PARTICLES THROUGH ADVECTION AND DIFFUSION

208 In our final experiment, we apply the previously obtained steady state velocity field $\mathbf{u}(\mathbf{x})$ in a study of
209 pollutant removal from Sample A. In particular, we perform a comparative, qualitative study of particle
210 evacuation rate from the porous sample, using two different flushing strategies: through continuous steady
211 flow and through the use of rectangular pulses of equal width and amplitude, increasing period and
212 decreasing duty cycle (see Fig. 5).

213 As the first step of this numerical experiment, we randomly seed a large number of particles N_0 (in our
214 experiments $N_0 = 250000$), uniformly distributed in the pore space of the sample. We assume that the
215 particles are passively advected by the fluid, but also undergo molecular diffusion. The motion of such
216 passive tracers is described by the following Langevin equation

$$\dot{\mathbf{x}}_k(t) = \bar{\mathbf{u}}(\mathbf{x}_k(t), t) + \boldsymbol{\eta}_k(t), \tag{18}$$

217 where $\mathbf{x}_k(t)$ is the position of the kth particle at time t, and $\bar{\mathbf{u}}(\mathbf{x}_k(t), t) = \mathbf{u}(\mathbf{x}_k(t))\psi(t)$ is the fluid's
218 velocity evaluated at particle's position at time t; $\psi(t)$ is the pulse envelope function. Here we assume that
219 the frequency of the pulses is smaller than the inverse of the characteristic time in which viscous effect
220 are propagated inside the porous sample. The latter can be estimated as R^2/ν, where R is on the order
221 of the largest channel width. The final term, $\boldsymbol{\eta}_k(t) = \sqrt{2D}\boldsymbol{\xi}(\mathbf{x}_k(t), t)$, is the random "kick" function,
222 where D is the diffusivity and $\boldsymbol{\xi}_k(t)$ is a vector-valued Gaussian noise with mean amplitude equal to
223 unity, whose correlation is given by $\langle \boldsymbol{\xi}_k(t)\boldsymbol{\xi}_{k'}(t') \rangle = \delta_{kk'}\delta(t - t')$. The above equation for passive tracers
224 can be obtained in the limit of vanishing Stokes time from the following system of Langevin equations
225 describing the Brownian motion of inertial particles in a moving fluid (**Cardy et al.**, 2008)

$$\dot{\mathbf{x}}_k(t) = \mathbf{v}_k(t), \quad \dot{\mathbf{v}}_k(t) = \frac{1}{\tau}\left(-\mathbf{v}_k(t) + \bar{\mathbf{u}}(\mathbf{x}_k(t), t) + \boldsymbol{\eta}_k(t)\right), \tag{19}$$

226 in which τ is the Stokes time. We integrate Eq. (18) for each particle using the forward Euler method.
227 Additionally we assume elastic collisions between the particles and the solid wall, and that the particles

228 which cross the outlet plane are removed from the system. Then, we track the number N of particles
229 remaining in the pore space as a function of the total volume of fluid flushed through the system

$$V(t) = \int_0^t \left(\int_{A_{in}} \bar{\mathbf{u}}(\mathbf{x}, t) \cdot d\mathbf{A} \right) dt. \tag{20}$$

230 The results of our experiments for Sample A are presented in Fig. 6. The parameters were chosen so that
231 the effective Péclet number $\mathrm{Pe} \approx 1600$. Evidently, continuous flushing is the least efficient in terms of
232 the amount of resources used (water, energy) in order to remove a given fraction of pollutant from the
233 sample. Increasing the separation between the pressure pulses yields increasingly more efficient use of
234 resources. This is due to the fact that the water flow through the sample quickly decreases the particle
235 concentration in the main channel network, however, some pores are inaccessible to the flow, i.e. $\mathbf{u} = 0$ in
236 such spaces. The only way for the particles to be released from these pores is through diffusion, and, as it
237 is a slower process, increasing the pulse separation increases the time for diffusion to act on. In contrast,
238 as the particle concentration in the main channel network decreases, the efficiency of continuous flushing
239 quickly drops.

4 DISCUSSION

4.1 EVALUATION OF THE ULBM

240 Our choice to use the unstructured lattice Boltzmann method, as opposed to the regular grid based
241 approaches, was dictated by the higher flexibility and accuracy of the unstructured meshes at representing
242 complex solid boundaries. Unlike regular grids, unstructured meshes allow for locating the nodes precisely
243 at the boundary, yielding the boundary approximation error on the order of h^2, as opposed to h in case
244 of regular grids, where h is the grid spacing (or local edge length, in case of unstructured meshes). This
245 error can be decreased further, without significantly increasing the problem size, by employing adaptive
246 meshes, i.e. using higher precision (lower h) to resolve fine features, while keeping the mesh coarser in the
247 regions where the boundary is almost flat, or where the flow field is approximately linear. Furthermore,
248 unstructured meshes do not introduce extra memory overhead related to the storage of the solid phase
249 elements, which is particularly beneficial in case of samples with low porosity. Overall, the number of
250 volumetric elements required to represent a porous structure with precision h on the boundary scales like
251 $h^{-2} \log h^{-1}$, as opposed to h^{-3} in case of basic regular grids. Certain techniques, such as the immersed
252 boundary method (**Chen et al.**, 2007) and hierarchical voxel structures (**Stiebler et al.**, 2008), allow
253 regular grid based approaches reach the effective storage efficiency similar to that of unstructured meshes.
254 However, they increase the complexity of the fluid simulation method, and the lack of coupling between
255 the nodal positions and the precise location of the solid boundary persists. As a consequence, boundary
256 features finer than the minimum grid spacing cannot be represented correctly and, in the worst case
257 scenario, the topology of the channel network might be ambiguous or inaccurate. In contrast, unstructured
258 grids yield much simpler formulation of the boundary conditions, allow for a faithful representation of
259 arbitrarily fine surface details, and reproduce the channel network topology exactly (although, in our case,
260 the accuracy of the representation is still limited by the resolution of the tomographic data).

261 The benefits of the ULBM come at a cost of increased number of computations per grid node. At each
262 time step, at a given node, regular grid based LBM requires a single evaluation of the collision term, one
263 assignment (copy) operation and a single addition per each discrete direction. ULBM also requires just
264 a single evaluation of the collision term per node, at every time step, however, the streaming and collision
265 steps require averaging the values of f_i and Ω_i from all neighbouring nodes, yielding $2(v + 1)$ additions
266 and multiplications per each discrete direction, where v is the valency of the node. In the meshes used
267 in our simulations, the average valency $\langle v \rangle \approx 12$ (Table 1). Finally, lattice Boltzmann methods compute
268 the full temporal evolution of the flow and, when applied to the problem of finding the steady-state flow
269 with constant pressure boundary condition, it converges asymptotically to the solution. Consequently,

270 in this particular application, it can be outperformed by implicit, finite-element Stokes solvers, which
271 typically require fewer sparse matrix multiplications (due to a lower number of variables, and a higher
272 convergence rate). However, implicit Stokes solvers are unsuitable for simulations of unsteady flows,
273 such as: multiphase flows, turbulent flows, flows influenced by moving solid boundaries or by oscillating
274 pressure differences, all of which do not pose a great difficulty for the LBM. Furthermore, the LBM's
275 convergence rate could be improved by employing more refined open boundary conditions, for example
276 by specifying the velocity profile at the inlet, and using Grad's approximation (**Chikatamarla et al.**,
277 2006) at the outlet.

4.2 CONCLUDING REMARKS

278 The complex pore geometry of most porous media is a significant obstacle for efficient numerical
279 simulation of flow. We have here discussed the unstructured lattice Boltzmann method for fluid flow. We
280 have used the method on a couple of rock samples and have in the sample with a more complex geometry
281 observed an anomalous dispersion of Lagrangian particles without any particle diffusion introduced. One
282 sample with a less complex pore space showed no sign of anomalous dispersion. We further showed that
283 in the more complex parts of the pore space, diffusive transport might dominate over advective transport
284 and therefore the evacuation of a pollutant might be, from a resource point of view, more effective if cycles
285 of flushing water through the sample are used. Further simulations however would be needed to establish
286 the most efficient strategy for pollutant removal.

DISCLOSURE/CONFLICT-OF-INTEREST STATEMENT

287 The authors declare that the research was conducted in the absence of any commercial or financial
288 relationships that could be construed as a potential conflict of interest.

FIGURES
Figure 1. On the left: The surface plot of the investigated volume of Sample A, colored according to the surface velocities. The values on the solid boundary are at least three orders of magnitude lower than the values on the outlet (top surface of the mesh). On the right: The streamlines of the steady-state velocity field, generated for $\tau = 0.02$, $\Delta\rho = 2.5 \cdot 10^{-6}$. Both images were generated using ParaView 4.3.1. (**Ayachit**, 2015)
Figure 2. On the left: The surface plot of the investigated volume of Sample B, colored according to the surface velocities. The values on the solid boundary are at least three orders of magnitude lower than the values on the outlet (top surface of the mesh). On the right: The streamlines of the steady-state velocity field, generated for $\tau = 0.1$, $\Delta\rho = 2.5 \cdot 10^{-6}$. Both images were generated using ParaView 4.3.1. (**Ayachit**, 2015)
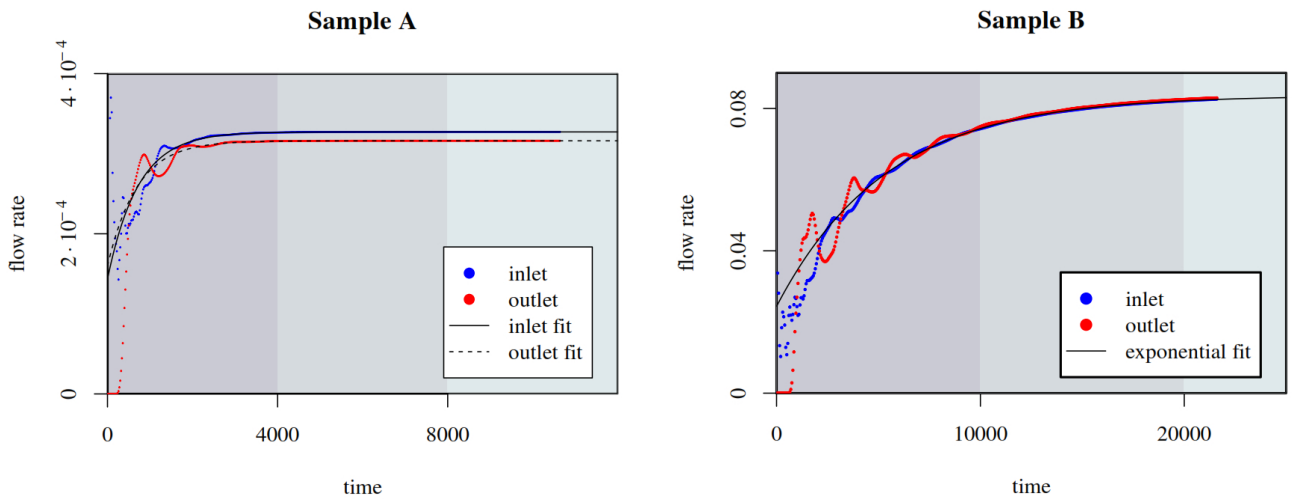

Figure 3. Convergence plot for the steady-state computation in Sample A (on the left, $\tau = 0.02$, $\Delta\rho = 10^{-6}$) and in Sample B (on the right, $\tau = 0.1$, $\Delta\rho = 2.5 \cdot 10^{-6}$). The exponential fits are computed in R, using robust nonlinear regression, after weighting out the initial, oscillatory phase (flow rates and time are given in lattice Boltzmann units).
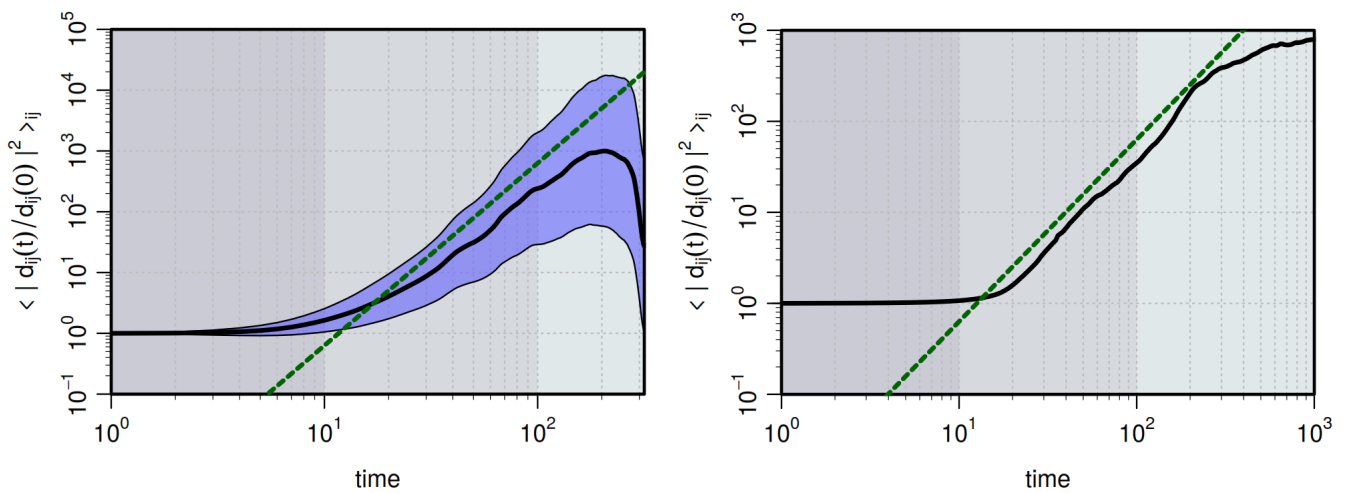

Figure 4. The black line shows the change with time of the average of the squared distance of particles, which initially are closer than 1% of the system size (the linear size). In the left panel, we show data from Sample A. The green dashed line is proportional to t^3 and is consistent with the Richardson dispersion law. Despite the limited scaling region, we see an anomalous dispersion, where particles separates faster than in a ballistic regime. The envelope surrounding the black line shows the standard deviation of individual particle pairs. In the right panel, we show similar data for Sample B. The dashed line is here proportional to t^2 and is therefore consistent with a ballistic separation of particles.
Figure 5. Continuous (blue) and rectangular pulse envelope (red). The pulse width T_{on} is constant in all our particle evacuation simulations, and we run the simulations with three different pulse separation times T_{off}. The duty cycle is defined as $d = T_{on}/T_{cycle}$. The pulse separation time T_{off} is on the order of 10% of the diffusive time, defined as R^2/D, where R is the characteristic pore size, and D is the diffusivity.
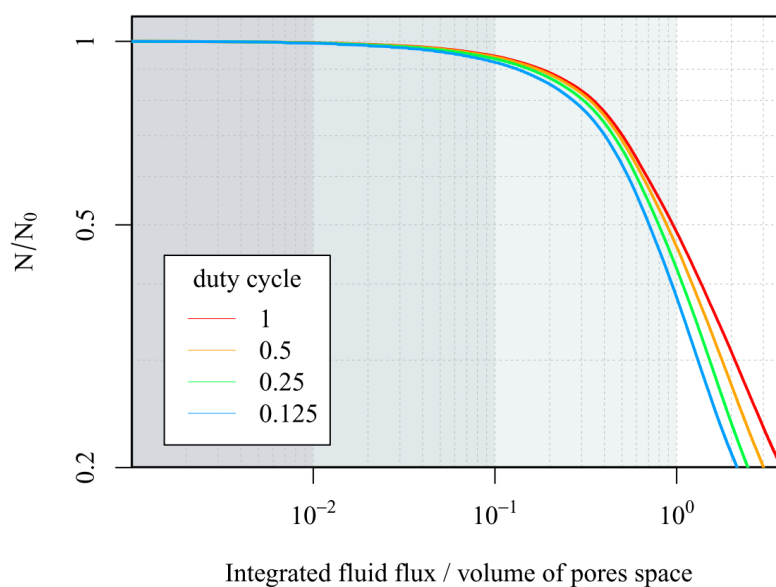

Figure 6. The fraction of the pollutant left inside Sample A as a function of the total volume of water that passed through the sample (given as a fraction of the pore space volume), using continuous flushing (duty cycle $d = 1$) and increasingly separated, constant width, rectangular pressure pulses.
